INTRODUCTION

Minimally invasive surgery has become a standard for colorectal cancer (CRC), except for locally advanced cancer or emergency surgery [1]. Laparoscopic surgery for CRC has the advantage of less blood loss, earlier bowel movement, shorter hospital stays, and lower complication rates than open approaches with similar oncologic outcomes [2–4]. However, in early colon cancer, it is often difficult to detect or localize small tumors during laparoscopic surgery. Laparoscopic surgery is less tactile than open surgery, making it difficult to find small endoluminal lesions that are difficult to find even in open surgery. Such difficulties in laparoscopic surgery may result in insufficient margins in CRC surgery and even lead to conversion to open surgery. For this reason, various methods for tumor localization have been described.

Tumor localization can be performed using intraoperative colo-
noscoposcopy (IOC) or preoperative colonoscopy (POC). IOC localization has the benefit of allowing the operator to measure the exact margin by simultaneously checking the laparoscopic and colonoscopy views. However, the operation time is delayed, and the inevitably distended bowel creates difficulty in the exposure of the surgical site [5]. Therefore, POC localization through peritumoral tattooing [6] with various agents, such as ink, indigo carmine, indocyanine green [7], or methylene blue, has been described.

Although POC localization provides convenience for operators, the use of dye has been controversial because of adverse effects, such as local inflammatory reactions, dye spillage, abscess formation, or anaphylaxis due to foreign body reactions [8]. To minimize the use of dye for POC, we introduced an autologous blood tattooing method previously used in upper and lower gastrointestinal operations [9]. This study aimed to evaluate the effectiveness and safety of autologous blood tattooing for POC localization based on the experience at our institution.

**METHODS**

**Ethics statement**

We conducted this study in compliance with the principles of the Declaration of Helsinki. After obtaining approval from the Institutional Review Board of St. Vincent Hospital at the Catholic University of Korea (No. VC22RISI0339), we retrospectively reviewed the patients' data and clinical information. The requirement for informed consent was waived due to the retrospective nature of the study.

**Description of participants**

From June 2019 to December 2021, 50 patients required POC localization of the neoplasm among the patients who were scheduled for elective colorectal resection. The indication for localization was early colon cancer (clinically T1 or T2) or colonic neoplasms that could not be resected endoscopically. All patients underwent preoperative evaluation, including a laboratory chemical study, electrocardiography, and abdomen, pelvis, and chest computed tomography (CT). Patients were excluded if they had undergone open surgery (not open conversion surgery) or if localization was not performed using autologous blood. Therefore, 5 patients were excluded (3, open surgery; 2, localization was performed using only a hemoclip), and finally, 45 patients were analyzed in this study.

**Protocol**

All patients took 4 L of Colyte (Taejoon Pharmaceutical) for bowel preparation in the morning on the day before surgery. The 18-gauge Angio needle was prepared for the immediate drawing of blood. Colonoscopy localization was performed by the colorectal surgeon the day before surgery in most cases. After the tip of the colonoscope reached the target lesion, 10 mL of blood was drawn from each patient. First, 1 to 2 mL of saline was injected in 4 directions of the whole bowel lumen at the level of the submucosa, then 2 to 3 mL of autologous blood was injected at the same site as saline injection (Fig. 1). After autologous blood injection, a hemoclip (Ez Clip, HX-610-135, Olympus) was placed distal to the injection site.

In the preoperative colonoscopy report, we defined the location of tumor as the following. (1) If the tumor was in the ascending (A) or descending (D) colon, we reported tumor location as proximal and distal A or D colon. The area from the cecum to hepatic flexure (HF) was designated as an A colon, the half of the A colon close to the cecum was defined as a proximal A colon, and the half close to HF was defined as a distal A colon.

![Fig. 1. Preoperative colonoscopic localization using autologous blood. (A) Early adenocarcinoma lesion. (B) Autologous blood tattooing was performed at the 4 directions of the peritumoral lesion. (C) Two hemoclips were placed.](https://doi.org/10.3393/ac.2023.00059.0008)
The area between the splenic flexure (SF) and descending-sigmoid junction (DSJ) was designated as a D colon. The D colon was classified into proximal and distal parts by applying the same principle as the A colon. (2) If the tumor was in the transverse (T) or sigmoid (S) colon, we reported the tumor location as proximal, mid, and distal T or S colon. The area from the HF to SF was designated as a T colon, and the area from the DSJ to the rectosigmoid junction was designated as an S colon. Then we measured the distance between the proximal and distal parts using the scale of the colonoscopy. After measuring the length of the colon, the length was divided into 1/3, and each was defined as a proximal, mid, or distal T or S colon.

After colonoscopy, an abdominal erect and kidney, ureter, and bladder (KUB) x-ray was performed to check for free air and confirm the localization site (Fig. 2).

Primary outcome
This study aimed to confirm the safety and efficacy of preoperative autologous colonoscopy tattooing in laparoscopic colorectal surgery. To confirm safety, we reviewed the complications that occurred due to the intervention immediately after colonoscopy and during surgery (bowel perforation, hemoperitoneum, mesenteric bleeding or hematoma, and abscess formation). To confirm its efficacy, we reviewed the agreement between the colonoscopy and surgical findings of the tumor location.

Statistical analysis
The Cohen unweighted κ-value was used to evaluate the agreement. The κ-values < 0 referred to no agreement; 0–0.20, slight agreement; 0.21–0.40, fair agreement; 0.41–0.60, moderate agreement; 0.61–0.80, substantial agreement; and 0.81–1.00, almost perfect agreement. Significance was defined as a P-value ≤ 0.05. Statistical analysis was performed using the IBM SPSS ver. 28.0 (IBM Corp). Repeated-measures analysis of variance was used to compare changes in hemoglobin (Hb) and white blood cell (WBC) counts before and after surgery between patients who underwent blood tattooing and those who did not.

RESULTS
Demographics and preoperative factors
POC localization using autologous blood was performed in 48 patients. With the exclusion of 3 patients who underwent open colectomy, 45 patients who underwent autologous blood tattooing and laparoscopic colectomy were included in this study. There was 1 case that was diagnosed as a rectal neuroendocrine tumor. However, the location was unclear as no definite anatomical landmarks were photographically documented. Therefore, we decided to perform the preoperative colonoscopy to confirm the exact location of the lesion and to localize the tumor. In the preoperative colonoscopy, the tumor was located 2-fold above the superior Houston valve, so the surgeon preoperatively diagnosed the tumor as a distal S colon, and we included this case in this study. The mean age of these patients was 62.42 ± 7.70 years, and 77.8% were men. The mean body mass index was 25.53 ± 2.66 kg/m², and 93.3% of the patients had American Society of Anesthesiologists (ASA) class I or II. In total, 71.7% of the tumors were invisible on preoperative abdominal and pelvic CT, and all tumors scheduled for surgical resection were confirmed using preoperative colonoscopy. Forty-two patients (93.3%) underwent colectomy due to colonic adenocarcinoma, 3 patients (6.7%) required surgical resection for colonic adenoma, which could not be removed endoscopically. Among 42 patients with colonic adenocarcinoma, 3 patients required POC localization for colonic adenoma in addition to primary cancer, so that the optimal resection margin could be determined intraoperatively. The mean interval between the preoperative colonoscopy and surgery was 20.80 ± 12.41 hours (range, 14–68 hours) (Table 1).

Pathologic outcomes
Among 45 patients, 3 patients had a benign polyp, and 42 had adenocarcinomas. 37 out of 42 patients (88.1%) with adenocarcinoma had early T category (pTis, T1, or T2) cancer. Among the 3
patients who were diagnosed the pT3 cancer, 2 were diagnosed with clinical T2 category on the CT scan, so the surgeon decided to localize the tumor. In 1 patient with T3 category, localization was performed in a separate T1 lesion. There were 2 T4 lesions, and localization was performed in separate benign lesions. In the 42 patients with adenocarcinoma, the proximal and distal margins were 9.43 ± 5.57 and 9.01 ± 9.84 cm, respectively.

Agreement between the findings

Table 2 shows the agreement between preoperative colonoscopy findings during the tattooing procedure and intraoperative surgical findings. The Cohen \( \kappa \)-value was 0.834, and according to the interpretation of the \( \kappa \)-value, the preoperative localization of colonic tumors using autologous blood was “almost perfectly agreed” with surgical findings. However, the agreement between the initial colonoscopy and surgical findings was “substantial” (\( \kappa = 0.733 \)), which was lower than that of the tattooing findings (Table 3). Most discrepancies were between the adjacent segments. However, there were 2 cases with discrepancies of more than 2 segments between the initial colonoscopy and surgical findings (proximal S to distal S colon and proximal D to proximal S colon).

Clinical outcomes of the autologous blood tattooing

All localization sites were visible in the laparoscopic view (Fig. 3), and there were no complications, such as bowel perforation, hemoperitoneum, or mesenteric hematoma. In 2 patients, a polyp that was missed by preoperative colonoscopy was discovered on intraoperative colonoscopy, which is performed to check the integrity of the anastomosis site.

We performed a subgroup analysis to obtain additional evidence regarding the safety of blood tattooing. We indirectly evaluated the risk of bleeding during or after colonoscopy blood tattooing by comparing changes in Hb levels before and after surgery. We also evaluated the possibility of an inflammatory response after tattooing by comparing changes in WBC. For statistical analysis, we assigned a control group to patients who were diagnosed and operated upon during the same period. A decrease in postoperative Hb and an increase in postoperative WBC were equally
The first endoscopic tattooing with India ink for the localization of colonic lesions was described in 1975 [10]. It is fascinating and useful, but has some adverse effects, including fat necrosis with inflammatory pseudotumor formation, colonic abscess, chronic inflammation, and adhesion formation caused by foreign body reaction [11–13]. Furthermore, this dye may disrupt the surgical plane because it can diffuse into the serosa and stain the mesentery or peritoneum [14, 15].

Other dyes, such as methylene blue, indigo carmine, and indocyanine green, have also been used for tumor localization. However, foreign body reactions were inevitable in these dyes, as well as in India ink.

Other methods do not use dyes, such as colonoscopy clipping, CT colonoscopy, or double-contrast barium enema. However, a metal clip is usually not observed in the laparoscopic field and is easily missed before surgery [16, 17], and imaging methods are unreliable in the localization of small tumors [18, 19].

For this reason, researchers devised using the patient’s own blood as a safe substance that can be visualized to replace the previous dyes and not cause foreign body reactions. Jeong et al. [9] implemented preoperative tumor localization using autologous blood tattooing for early gastric cancer for the first time, proving the usefulness of this simple method. Yeo et al. [20] also reported the safety and feasibility of localization using a patient’s own blood.

At our institution, colorectal surgeons routinely perform colonoscopies for follow-up patients who have undergone colorectal surgery and perform procedures, such as biopsy and endoscopic mucosal resection (EMR). We previously used indigo carmine for colonoscopy tattooing, not routinely, but according to the surgeon’s discretion. However, since 2019, autologous blood tattooing...
has been routinely used for early CRC or polyps that require surgical resection.

In the patients who underwent localization using autologous blood, there were no cases in which the tattooing lesion was not visible in the laparoscopic view. It is known that the tattooed lesions on the mesenteric border or retroperitoneal side are less visible [21, 22]. These promising results in our study might be because tattooing was always performed in 4 directions of the intestinal lumen, and therefore, at least 1 tattooed site could be observed.

For a safe procedure, we targeted the submucosa for injection and injected saline just before blood tattooing, which is the same method as injection-assisted EMR [23]. In addition, we routinely performed chest radiography, erect abdominal, and KUB radiography to check for the presence of free air, which indicated a perforated abdominal viscus. We also confirmed the location of the localization site by checking metal clips placed immediately next to the tumor. Radiographs showed no evidence of intestinal perforation. Finally, during the operation, surgeons did not find any complications, such as bowel perforation, peritonitis, hemoperitoneum, or mesenteric hematoma.

Furthermore, in the subgroup analysis, the degree of Hb and WBC changes before and after surgery did not differ significantly between patients who underwent colonoscopy and those who did not. These results suggest that the tattooing procedure does not increase the risk of bleeding or inflammation. Based on the results of this study, a series of processes are essential for safe tattooing. First, the scopist should set the target of injection to the submucosa. Then blood injection should be performed after saline injection. Finally, after the procedure, the scopist should check the chest, abdomen, and KUB radiographs to confirm any complications or location markers.

We also compared tumor locations confirmed during colonoscopy localization with those identified during laparoscopic surgery. The \( \kappa \)-value between the 2 methods was 0.834, indicating almost perfect agreement. Even in cases of disagreement between the colonoscopy and surgical findings, the location disparity was slight (e.g., mid vs. distal S colon); therefore, there was no change in the surgical plan during the operation due to incorrect localization. In contrast, the degree of agreement between the initial colonoscopy and surgical findings was lower. In addition, a serious disparity was observed between the initial colonoscopy and surgical findings of the 2 patients. In 1 patient, the surgical method was changed after tattooing.

This discordance was related to various factors. Some anatomical features, such as colonic elongation, redundancy, and tortuosity, are well known to be associated with difficulties or failure during colonoscopy [24]. In addition, the colonoscopy technique itself depends on the operator. For example, the insertion length required to reach the DSJ is within 40 cm when experts perform colonoscopy using the shortening technique, but the length can be increased to 60 cm or more [25]. This is why photographic documentation of tumor with anatomical landmark and detailed description is essential. Therefore, setting the surgical strategy using only the description of initial colonoscopy findings is limited [22, 26]. When colon resection is performed based only on the...
In conclusion, preoperative colonoscopy localization is necessary for small endoluminal lesions, particularly those in the T or S colon. Autologous blood is a safe and effective agent for localizing materials that can replace previous dyes. In addition, using autologous blood in the tattooing procedure has some benefits in that there is no concern about supply and demand instability or foreign body reactions. Therefore, in this study, colonoscopy autologous blood tattooing was a safe and feasible procedure for the localization of early colon cancer or colonic neoplasms. However, a large prospective case-control study is required for the routine application of this procedure in early colon cancer or colonic neoplasms.
